

Simple linear regression

David Puelz

Regression: General introduction

- Regression analysis is the most widely used statistical tool for understanding relationships among variables
- It provides a conceptually simple method for investigating functional relationships between one or more factors and an outcome of interest
- The relationship is expressed in the form of an equation or a model connecting the response or dependent variable and one or more explanatory or predictor variable

Why?

Straight prediction questions:

- For who much will my house sell?
- How many runs per game will the Red Sox score this year?
- Will this person like that movie? (Netflix rating system)

Explanation and understanding:

- What is the impact of MBA on income?
- How does the returns of a mutual fund relates to the market?
- Does Walmart discriminates against women regarding salaries?

1st Example: Predicting house prices

Problem:

- Predict market price based on observed characteristics

Solution:

- Look at property sales data where we know the price and some observed characteristics.
- Build a decision rule that predicts price as a function of the observed characteristics.

What characteristics do we use?

We have to define the variables of interest and develop a specific quantitative measure of these variables

- Many factors or variables affect the price of a house
 - size
 - number of baths
 - garage, air conditioning, etc
 - neighborhood

To keep things super simple, let's focus only on size.

The value that we seek to predict is called the dependent (or output) variable, and we denote this:

- Y =price of house (e.g. thousands of dollars)

The variable that we use to guide prediction is the explanatory (or input) variable, and this is labelled

-X =size of house (e.g. thousands of square feet)

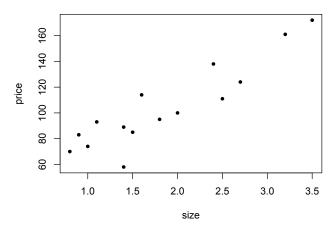

What does this data look like?

Size		Price	
	0.80		70
	0.90		83
	1.00		74
	1.10		93
	1.40		89
	1.40		58
	1.50		85
	1.60		114
	1.80		95
	2.00		100
	2.40		138
	2.50		111
	2.70		124
	3.20		161
	3.50		172

It is much more useful to look at a scatterplot

In other words, view the data as points in the $X \times Y$ plane.

Regression model

Y = response or outcome variable X = explanatory or input variables

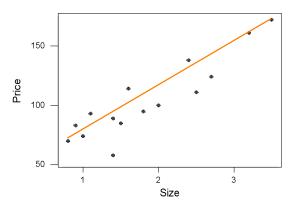

A linear relationship is written

$$Y = b_0 + b_1 X + e$$

There seems to be a linear relationship between price and size:

As size goes up, price goes up.

The line shown was fit by the "eyeball" method.

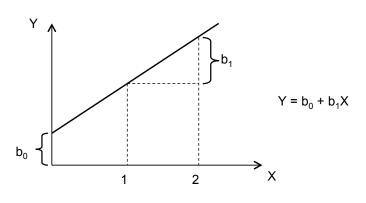

Recall that the equation of a line is:

$$Y = b_0 + b_1 X + e$$

Where b_0 is the intercept and b_1 is the slope.

The intercept value is in units of Y (\$1,000). The slope is in units of Y per units of X (\$1,000/1,000 sq ft). The residual e is in units of Y (\$1,000).

Our "eyeball" line has $b_0 = 35$, $b_1 = 40$.

We can now predict the price of a house when we know only the size; just read the value off the line that we've drawn.

For example, given a house with of size X = 2.2.

Predicted price $\hat{Y} = 35 + 40(2.2) = 123$.

Note: Conversion from 1,000 sq ft to \$1,000 is done for us by the slope coefficient (b_1)

Can we do better than the eyeball method?

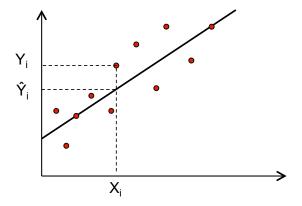

We desire a strategy for estimating the slope and intercept parameters in the model $\hat{Y} = b_0 + b_1 X$

A reasonable way to fit a line is to minimize the amount by which the fitted value differs from the actual value.

This amount is called the residual.

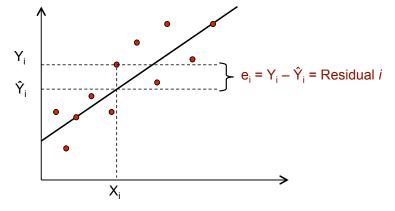

What is the "fitted value"?

The dots are the observed values and the line represents our fitted values given by $\hat{Y}_i = b_0 + b_1 X_1$.

What is the "residual" for the *i*th observation'?

We can write
$$Y_i = \hat{Y}_i + (Y_i - \hat{Y}_i) = \hat{Y}_i + e_i$$
.

Least squares

Ideally we want to minimize the size of all residuals:

- If they were all zero we would have a perfect line.
- Trade-off between moving closer to some points and at the same time moving away from other points.

The line fitting process:

- Give weights to all of the residuals.
- Minimize the "total" of residuals to get best fit.

Least Squares chooses b_0 and b_1 to minimize $\sum_{i=1}^{N} e_i^2$

$$\sum_{i=1}^{N} e_i^2 = e_1^2 + e_2^2 + \dots + e_N^2 = (Y_1 - \hat{Y}_1)^2 + (Y_2 - \hat{Y}_2)^2 + \dots + (Y_N - \hat{Y}_N)^2$$

Least squares – excel Output

Size	35.38596255	4.494082942	7.873900638	2.65987E-06	25.67708664	45.09483846

2nd Example: Offensive performance in baseball

- Problems:

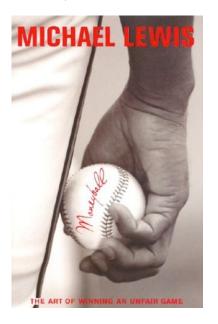

- Evaluate/compare traditional measures of offensive performance
- Help evaluate the worth of a player

- Solutions:

 Compare prediction rules that forecast runs as a function of either AVG (batting average), SLG (slugging percentage) or OBP (on base percentage)

2nd Example: Offensive performance in baseball

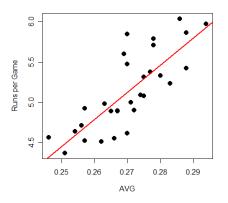

Baseball data - using AVG

Each observation corresponds to a team in MLB. Each quantity is the average over a season.

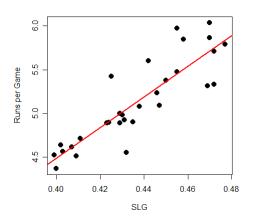

- Y = runs per game; X = AVG (average)

LS fit: Runs/Game = -3.93 + 33.57 AVG

Baseball data - using SLG

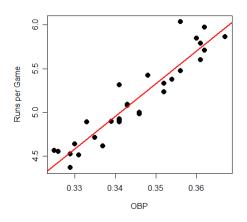

- -Y = runs per game
- X = SLG (slugging percentage)

LS fit: Runs/Game = -2.52 + 17.54 SLG

Baseball data – using OBP

- -Y = runs per game
- -X = OBP (on base percentage)

LS fit: Runs/Game = -7.78 + 37.46 OBP

Baseball data

- What is the best prediction rule?
- Let's compare the predictive ability of each model using the average squared error

$$\sqrt{\frac{1}{N}\sum_{i=1}^{N}e_{i}^{2}} = \sqrt{\frac{\sum_{i=1}^{N}\left(\widehat{Runs_{i}} - Runs_{i}\right)^{2}}{N}}$$

Place your money on OBP!!

	Root Average Squared Error
AVG	0.29
SLG	0.23
OBP	0.16

Estimation of error variance

We can quantify the variability around the line by computing the variance of the residuals:

$$s = \sqrt{\frac{1}{n-2} \sum_{i=1}^{n} e_i^2} = \sqrt{\frac{\sum (Y_i - \hat{Y}_i)^2}{n-2}}$$

This is measured in the same units as Y. It's also called the regression standard error.

(Don't worry about this n-2 yet!).

$$R^2 = 0.82$$

The simple linear regression model

The power of statistical inference comes from the ability to make precise statements about the accuracy of the forecasts.

In order to do this we must invest in a probability model.

Simple Linear Regression Model:
$$Y = \beta_0 + \beta_1 X + \varepsilon$$

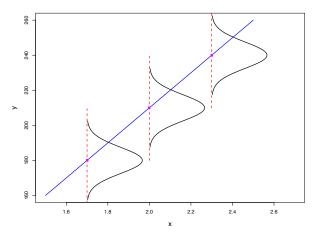

$$\varepsilon \sim \mathrm{N}(0, \sigma^2)$$

- $-\beta_0 + \beta_1 X$ represents the "true line"; The part of Y that depends on X.
- The error term ε is independent "idosyncratic noise"; The part of Y not associated with X.

The simple linear regression model

The conditional distribution for Y given X is Normal:

$$Y|X = x \sim N(\beta_0 + \beta_1 x, \sigma^2).$$

Size	35.38596255	4.494082942	7.873900638	2.65987E-06	25.67708664	45.09483846

Sampling distribution of least squares estimates

How much do our estimates depend on the particular random sample that we happen to observe? Imagine:

- Randomly draw different samples of the same size.
- For each sample, compute the estimates b_0 , b_1 , and s.

If the estimates don't vary much from sample to sample, then it doesn't matter which sample you happen to observe.

If the estimates do vary a lot, then it matters which sample you happen to observe.

Sampling distribution of b_1

The sampling distribution of b_1 describes how estimator $b_1 = \hat{\beta}_1$ varies over different samples with the X values fixed.

It turns out that b_1 is normally distributed (approximately): $b_1 \sim N(\beta_1, s_{b_1}^2)$.

- b_1 is unbiased: $E[b_1] = \beta_1$.
- s_{b_1} is the standard error of b_1 . In general, the standard error is the standard deviation of an estimate. It determines how close b_1 is to β_1 .
- This is a number directly available from the regression output.

Confidence intervals

Since $b_1 \sim N(\beta_1, s_{b_1}^2)$, Thus:

- 68% Confidence Interval: $b_1 \pm 1 \times s_{b_1}$
- 95% Confidence Interval: $b_1 \pm 2 \times s_{b_1}$
- 99% Confidence Interval: $b_1 \pm 3 \times s_{b_1}$

Same thing for b_0

- 95% Confidence interval: $b_0 \pm 2 \times s_{b_0}$

The confidence interval provides you with a set of plausible values for the parameters

$$[b_1 - 2 \times s_{b_1}; b_1 + 2 \times s_{b_1}] \approx [25.67; 45.09]$$

Testing

Suppose we want to assess whether or not β_1 equals a proposed value β_1^0 . This is called hypothesis testing.

Formally we test the null hypothesis:

 $H_0: \beta_1 = \beta_1^0$

vs. the alternative

 $H_1: \beta_1 \neq \beta_1^0$

Testing, just like last time!

That are 2 ways we can think about testing:

1. Building a test statistic... the t-stat,

$$t = \frac{b_1 - \beta_1^0}{s_{b_1}}$$

This quantity measures how many standard deviations the estimate (b_1) from the proposed value (β_1^0) .

If the absolute value of t is greater than 2, we need to worry (why?)... we reject the hypothesis.

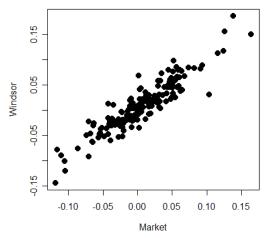

2. Looking at the confidence interval. If the proposed value is outside the confidence interval you reject the hypothesis.

Notice that this is equivalent to the t-stat. An absolute value for *t* greater than 2 implies that the proposed value is outside the confidence interval... therefore reject.

Let's investigate the performance of the Windsor Fund, an aggressive large cap fund by Vanguard...

The plot shows monthly returns for Windsor vs. the S&P500

Consider a CAPM regression for the Windsor mutual fund.

$$r_{\rm w} = \beta_0 + \beta_1 r_{\rm sp500} + \epsilon$$

Let's first test $\beta_1 = 0$

 H_0 : $\beta_1 = 0$. Is the Windsor fund related to the market?

 $H_1: \beta_1 \neq 0$

Regression Statistics						
Multiple R	0.923417768					
R Square	0.852700374					
Adjusted R Square	0.851872848					
Standard Error	0.018720015					
Observations	180					

ANOVA					
	df	SS	MS	F	Significance F
Regression		0.3611	0.361099761	1030.421266	6.0291E-76
Residual	17	0.062378	0.000350439		
Total	17	0.423478			

- -t = 32.10... reject $\beta_1 = 0!!$
- the 95% confidence interval is [0.87; 0.99]... again, reject!!

Now let's test $\beta_1 = 1$. What does that mean?

 H_0 : $\beta_1 = 1$ Windsor is as risky as the market.

 H_1 : $\beta_1 \neq 1$ and Windsor softens or exaggerates market moves.

We are asking whether or not Windsor moves in a different way than the market (e.g., is it more conservative?).

 reject.

 the 95% confidence interval is [0.87; 0.99]... again, reject, but...

- The p-value provides a measure of how weird your estimate is if the null hypothesis is true
- Small p-values are evidence against the null hypothesis
- In the AVG vs. Runs per Game example... H_0 : $\beta_1 = 0$. How weird is our estimate of $b_1 = 33.57$?
- Remember: $b_1 \sim N(\beta_1, s_{b_1}^2)...$ If the null was true $(\beta_1 = 0)$, $b_1 \sim N(0, s_{b_1}^2)$

- Where is 33.57 in the picture below?

The *p*-value is the probability of seeing b_1 equal or greater than 33.57 in absolute terms. Here, *p*-value=0.000000124!!

Small p-value = bad null!

$- H_0: \beta_1 = 0... \text{ p-value} = 1.24\text{E-}07... \text{ reject!}$

SUMMARY OUTPUT

Regression Statistics

Testing – summary

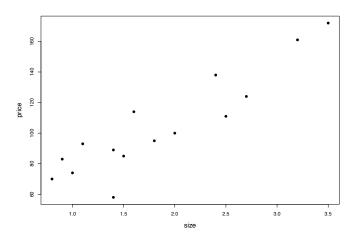

- Large t or small p-value mean the same thing...
- p-value < 0.05 is equivalent to a t-stat > 2 in absolute value
- Small p-value means something weird happen if the null hypothesis was true...
- − Bottom line, small p-value → REJECT! Large t → REJECT!
- But remember, always look at the confidence interveal!

- $R^2 = 82\%$
- Great R^2 , we are happy using this model to predict house prices, right?

House data – one more time!

- But, s = 14 leading to a predictive interval width of about US\$60,000!! How do you feel about the model now?
- As a practical matter, s is a much more relevant quantity than R². Once again, intervals are your friend!
